Abstract

This paper presents Natjam, a system that supports arbitrary job priorities, hard real-time scheduling, and efficient preemption for Mapreduce clusters that are resource-constrained. Our contributions include: i) exploration and evaluation of smart eviction policies for jobs and for tasks, based on resource usage, task runtime, and job deadlines; and ii) a work-conserving task preemption mechanism for Mapreduce. We incorporated Natjam into the Hadoop YARN scheduler framework (in Hadoop 0.23). We present experiments from deployments on a test cluster, Emulab and a Yahoo! Inc. commercial cluster, using both synthetic workloads as well as Hadoop cluster traces from Yahoo!. Our results reveal that Natjam incurs overheads as low as 7%, and is preferable to existing approaches.

1 Introduction

Today, computation clusters running engines such as Apache Hadoop [16, 22], Dryad Linq [56], DOT [25], Hive [51], and Pig Latin [38] are used to process a variety of big datasets. The batch Mapreduce jobs in these clusters have priority levels or deadlines. For instance, a job with a high priority (or short deadline) may be one that processes click-through logs and differentiates ads that have reached their advertiser target from ads that are good to show now. For such jobs, it is critical to produce timely results, since it directly affects revenue. On the other hand, a lower priority (or long deadline) job may, for instance, identify more lucrative ad placement patterns via a machine learning algorithm on long-term historical click data. The latter jobs affect revenue indirectly and therefore they need to complete soon, but they must be treated at a lower priority than the former jobs.

The most common use case is a *dual priority* setting, with only two priority levels – high priority jobs and low priority jobs. We call the high priority jobs as *production jobs* and the low priority ones as *research jobs* [1]. A popular approach among organizations to solve this problem is to provision two physically-separate clusters, one for production jobs and one for research jobs. Administrators tightly restrict the workloads allowed on the production cluster, perform admission control manually based on deadlines, keep track of deadline violations via alert systems such as pagers, and subsequently readjust job and cluster parameters manually.

Besides the intensive human involvement, the approach above suffers from: i) long job completion times, and ii) inefficient resource utilization. For instance, jobs in an overloaded production cluster might take longer, even though the research cluster is underutilized (and vice-versa). In fact Mapreduce cluster workloads

[1]This terminology is from our use cases.

are time-varying and unpredictable, e.g., in the Yahoo! Hadoop traces we use in this paper, hourly job arrival rates exhibited a max-min ratio as high as 30. Thus, there are times when the cluster is *resource-constrained*, i.e., it has insufficient resources to meet incoming demand. Since physically separate clusters cannot reclaim resources from each other, the infrastructure's overall resource utilization stays sub-optimal.

The goals of this paper are: 1) to run a consolidated Mapreduce cluster that supports all jobs, regardless of their priority or deadline; 2) to achieve low completion times for higher priority jobs; 3) while still optimizing completion times of lower priority jobs. The benefits are high cluster resource utilization, and thus reduced capital and operational expenses.

We present a system called Natjam [2] that achieves the above goals, and which we have integrated into the Hadoop YARN scheduler (Hadoop 0.23). Natjam's first challenge is to build a unified scheduler for all job priorities and deadlines in a way that fluidly manages resources among a heterogeneous mix of jobs. When a higher priority job arrives into a full cluster, today's approaches involve either killing lower priority jobs' tasks [11, 24], or waiting for the same to finish [23]. The former approach prolongs low priority jobs because they repeat work, while the latter prolongs high priority jobs. Natjam solves this by using an *on-demand checkpointing* technique that saves the state of a task when it is preempted, so that it can resume where it left off when resources become available. This checkpointing is fast, inexpensive, and automatic in that it requires no programmer involvement.

Natjam's second challenge is the desire to have high priority jobs finish quickly, but not at the expense of extending many low priority jobs' completion times. Natjam addresses this by leveraging smart *eviction* policies that select which low priority jobs and their constituent tasks are affected by arriving high priority jobs. Natjam uses a two-level eviction approach – it first selects a victim job (job eviction policy) and then within that job, one or more victim tasks (task eviction policy). For the dual priority setting with only two priority levels, our eviction policies take into account: i) resources utilized by a job, and ii) time remaining in a task. We then generalize to arbitrary real-time job deadlines via eviction policies based on both a job's deadline and its resource usage.

We present experimental results from deployments on a test cluster, on Emulab and on a commercial cluster at Yahoo!. Our experiments use both synthetic workloads and Hadoop workloads from Yahoo! Inc. We evaluate various eviction policies, and our study shows that compared to traditional multiprocessor environments, eviction policies have counter-intuitive behavior in Mapreduce environments, e.g., we discovered that longest-task first scheduling is optimal for Mapreduce environments. For the dual priority setting, Natjam incurs overheads of under 7% for all jobs. For the real-time setting with arbitrary deadlines, our generalized system called Natjam-R meets deadlines with only 20% extra laxity in the deadline compared to the job runtime.

While we will discuss related work in Section 10, we briefly discuss at a high level how our work is placed. Our focus is on batch jobs rather than streaming or interactive workloads [2, 13, 14, 42, 48, 49]. Some systems have looked at preemption in Mapreduce [6], w.r.t. fairness [27], at intelligent killing of tasks [11] (including the Hadoop Fair Scheduler [24]), and SLOs (Service Level Objectives) in generic cluster management [1, 32, 46]. In comparison our work is the first to study the effect of eviction policies and deadline-based scheduling for resource-constrained Mapreduce clusters. Our strategies can be applied orthogonally in systems like Amoeba [6]. We are also the first to incorporate such support directly into Hadoop YARN. Finally, Mapreduce deadline scheduling has been studied in infinite clusters [19, 40, 52, 55] but not in resource-constrained clusters.

2 Eviction Policies for a Dual Priority Setting

In the first part of the paper, we focus purely on the dual priority setting. This section presents eviction policies and the following section the systems architecture for the same. Later Section 4 generalizes this to multiple priorities.

Eviction policies lie at the heart of Natjam. When a production (high priority) Mapreduce job arrives at a resource-constrained cluster and there are insufficient resources to schedule it, some tasks of research (low priority) Mapreduce jobs need to be preempted. Our goals here are to minimize job completion times both for production and for research jobs. This section addresses the twin questions of: 1) How is a victim (research) job chosen so that some of its tasks can be preempted, and 2) Within a given victim job, how are victim task(s) chosen for preemption. We call these as *job eviction* and *task eviction* policies respectively.

The job and task eviction policies are applied in tandem, i.e., for each required task of the arriving production job, a running research task is evicted by applying the job eviction policy first followed by the task eviction policy. This means that a research job chosen as victim may only be evicted partially, i.e., some of its tasks may continue running, e.g., if the arriving job is relatively

[2]Natjam is the Korean word for nap.

smaller, or if the eviction policy also picks other victim research jobs.

2.1 Job Eviction Policies

The choice of victim job affects completion time of lower priority research jobs by altering resources already allocated to them. Thus job eviction policies need to be sensitive to current resource usage of individual research jobs. We discuss three resource-aware job eviction policies.

Most Resources (MR): This policy chooses as victim that research job which is currently using the most resources inside the cluster. In Hadoop YARN, this means the number of containers used by the job, while in other versions of Mapreduce this refers to the number of cluster slots [3].

The MR policy, loosely akin to worst-fit policy in OS segmentation, is motivated by the need to evict as few research jobs as possible – a large research job may contain sufficient resources to accommodate one large production job or multiple small production jobs. Thus, fewer research jobs are deferred, more of them complete earlier, and average research job completion time is minimized.

The downside of the MR policy is that when there is one large research job (as might be the case with heavy tailed distributions), it is always victimized whenever a production job arrives. This may lead to starvation and thus longer completion times for large research jobs.

Least Resources (LR): In order to prevent starving large research jobs, this policy chooses as victim that research job which is currently using the least resources inside the cluster. The rationale here is that small research jobs which are preempted can always find resources if the cluster frees up even a little in the future. However, the LR policy can cause starvation for small research jobs if the cluster stays overloaded, e.g., if a new production job arrives whenever one completes, LR will pick the same smallest jobs for eviction each time.

Probabilistically-weighted on Resources (PR): In order to address the starvation issues of LR and MR, our third policy called PR selects a victim job using a probabilistic metric based on resource usage. In PR, the probability of choosing a job as a victim is directly proportional to the resources it currently holds. Effectively, PR treats all tasks identically for eviction, i.e., if the task eviction policy were random, the chance of eviction for each task is identical and independent of its job. The downside of PR is that it spreads out evictions across multiple jobs – unlike MR, in PR one incoming production job may slow down multiple research jobs.

The latter half of this paper compares these job eviction policies experimentally.

[3]While our approach is amenable to finer-grained notions of resources, resulting issues such as fragmentation are beyond the scope of this paper. Thus we use containers that are equi-sized.

2.2 Task Eviction Policies

Once a victim job has been selected, the task eviction policy is applied within that job to select one task that will be preempted (i.e., suspended).

Our approach makes three assumptions based on use case studies: i) Reduces are long enough so that preempting a task takes less time than the task itself; ii) Only Reduce tasks are preempted; iii) Reduces are stateless in between keys. For instance, in Facebook workloads the median Reduce task takes 231 s [58], substantially longer than the time to preempt a task (Section 5). Our focus on preemption of only reduces is due to two reasons: 1) The challenge of checkpointing reduce tasks subsumes that of checkpointing map tasks, since a map processes individual key-value pairs while a reduce processes batches of them. 2) Several use case studies have revealed that reduces are substantially longer than maps and thus have a bigger effect on the job tail. In the same Facebook trace above, the median map task time is only 19 s. While 27.1 map containers are freed per second, only 3 (out of 3100) reduce containers are freed per second. Thus a small production job with 30 reduces would wait on average 10 s, and a large job with 3000 reduces waits 1000 s. Finally, the traditional stateless reduce approach is used in many Mapreduce programs – however, Natjam could be extended to support stateful reducers (Section 9).

A Mapreduce research job's completion time is determined by its last finishing reduce task. A long tail, or even a single task that finishes late, will extend the research job's completion time. This concern implies that tasks with shorter remaining time (for execution) must be evicted first. However in multiprocessors shortest-task-first scheduling is known to be optimal [50] – in our context this means that the task with the longer remaining time must be evicted first. This motivates two contrasting task eviction policies.

Shortest Remaining Time (SRT): In this policy, tasks that have the shortest remaining time are selected to be suspended. This policy aims to minimize the impact on the tail of a research job. Further, a task suspended by SRT will finish quickly once it has been resumed. Thus SRT is loosely akin to the longest-task first strategy in multiprocessor scheduling. Rather counter-intuitively, SRT is provably optimal under certain conditions:

Theorem 2.1: Consider a system where a production job arrival affects exactly one victim job, and evicts several tasks from it. If all these evicted tasks are resumed si-

multaneously in the future, and we ignore speculative execution, then the SRT eviction policy results in an optimal (lowest) completion time for that research job.

Proof: No alternative policy can do better than SRT in two sub-metrics: i) sum of time remaining for evicted tasks, and ii) tail (i.e., max) of time remaining among the evicted tasks. Thus, when the evicted tasks resume simultaneously, an alternative eviction policy can do only as well as SRT in terms of completion time of the research job. □

We note that the assumption, that tasks of the victim job are resumed simultaneously, is reasonable in those real-life scenarios where production job submission times and sizes are unpredictable. Our experiments also validated this theorem.

Longest Remaining Time (LRT): In this policy, the task with the longest remaining time is chosen to be suspended earlier. This policy is loosely akin to shortest-task first scheduling in multiprocessors. Its main advantage over SRT is that it is less selfish and frees up more resources earlier. LRT might thus be useful in scenarios where production job arrivals are bursty. Consider a victim job containing two tasks – one short and one with a long remaining time. SRT evicts the the shorter task, freeing up resources for one production task. LRT evicts the longer task, but the shorter unevicted task will finish soon anyway, thus releasing resources for *two* production tasks, while incurring only one task suspend overhead. However, LRT can lengthen the tail of the research job, increasing its completion time.

The latter half of this paper compares these task eviction policies experimentally.

3 Natjam Architecture

In order to understand the design decisions required to build eviction policies into a Mapreduce cluster management system, we incorporated Natjam into the popular Hadoop YARN framework in Hadoop 0.23. We now describe Natjam's architecture, focusing on the dual priority setting (production and research jobs).

3.1 Preemption in Hadoop YARN

Background – Hadoop YARN Architecture: In the Hadoop YARN architecture, a single cluster-wide Resource Manager (RM) performs resource management. It is assisted by one Node Manager (NM) per node (server). The RM receives periodic heartbeats from each NM containing status updates about resource usage and availability at that node.

The RM runs the Hadoop Capacity Scheduler. The Capacity Scheduler maintains multiple queues which contain jobs. An incoming job is submitted to one of these queues. An administrator can configure two capacities per queue – a minimum (guaranteed) capacity, and a maximum capacity. The scheduler varies the queue capacity between these two queues based on the jobs that have arrived into them.

The basic unit of resource allocation for a task is called a *container*. A container is effectively a resource slot that contains sufficient resources (primarily memory) to run one task – either a map, or a reduce, or a master task. An example master task is the Application Master (AM), which is allocated one container. One AM is assigned to each Mapreduce job, and performs job management functions.

An AM requests and receives, from the RM, container allocations for its tasks. The AM assigns a task to each container it receives, and sends launch requests to the container's NM. It also performs speculative execution where needed.

An AM sends heartbeats to the RM. The AM also receives periodic heartbeats from its tasks. For efficiency, YARN piggybacks control traffic (e.g., container requests, task assignments) atop heartbeat messages.

Natjam Components: Natjam entails changes to the Hadoop Capacity Scheduler (at the RM) and the AM, while the NM stays unchanged. Concretely, Natjam adds the following new components to Hadoop YARN:

1. Preemptor: The preemptor is a part of the RM. We configure the Capacity Scheduler to contain two queues – one for production jobs and one for research jobs. The preemptor makes preemption decisions by using job eviction policies.

2. Releaser: This component is a part of each AM, and is responsible for running the task eviction policies.

When we modify Hadoop, instead of adding new messages that will incur overhead, Natjam leverages and piggybacks atop YARN's existing heartbeats for efficiency. The tradeoff is a small scheduling delay, but our experiments show that such delays are small.

We later detail these two components in Section 3.2. Now we show how preemption and checkpointing work.

Natjam's Preemption Mechanism – Example: We illustrate how Natjam's preemption works in YARN. Fig. 1 depicts an example where a research Job 2 is initially executing in a full cluster, when a production Job 1 requires a single container. [4] The steps in the figure are as follows:

Step 1: On AM1's heartbeat, it asks the RM to allocate one container.

Steps 2, 3: The cluster is full, so the RM applies the job eviction policies and selects Job 2 as victim.

Step 4: The Preemptor waits for AM2's next heartbeat,

[4] For simplicity we assume AM1 (of Job 1) already has a container.

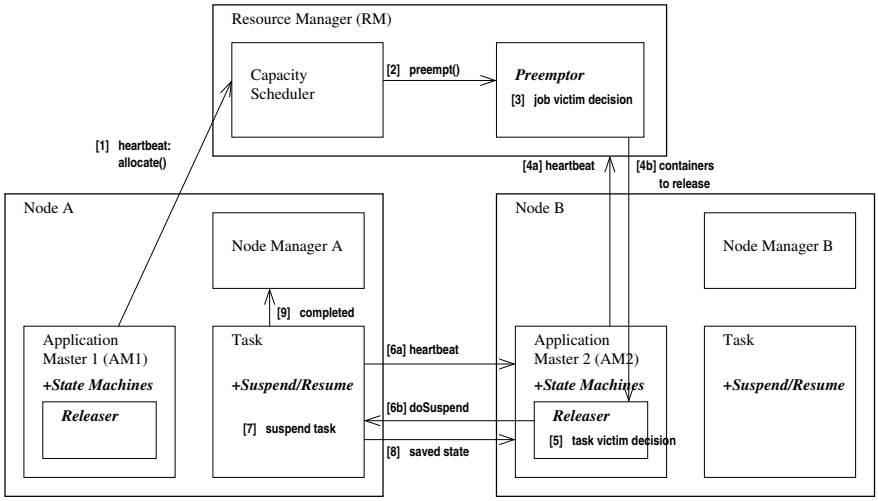

Figure 1: Example: Container Suspend in Natjam. *New components are shown in bold font; others are from YARN. AM1 is a production job, AM2 is a research job.*

and in response sends AM2 the number and type of containers to be released.
Step 5: The Releaser at AM2 uses the task eviction policy to select a victim task.
Step 6: When the victim task (still running) sends its next usual heartbeat to AM2, it is asked to suspend.
Step 7: The victim task suspends and saves a checkpoint.
Step 8: The victim task sends the checkpoint to AM2.
Step 9: The task indicates to NM-A that it has completed and it exits, freeing the container.

This ends the Natjam-specific steps. For completeness, we list below the remaining steps taken by default YARN to give AM1 the new container.
Step 10: NM-A's heartbeat sends container to RM.
Step 11: AM1's next RM heartbeat gets container.
Step 12: AM1 sends NM-A the task request.
Step 13: NM-A launches the task on the container.

Checkpoint Saved and used by Natjam: When Natjam suspends a research job's reduce task, an on-demand checkpoint is saved automatically. It contains the following items: i) An ordered *list of past suspended container IDs*, one for each attempt, i.e., each time this task was suspended in the past; ii) *Key counter*, i.e., number of keys that have been processed so far; iii) *Reduce input paths*, i.e., local file path; iv) *Hostname* of last suspended attempt – this is useful for preferrably resuming the research task on the same server.

Natjam also leverages intermediate task data already available via Hadoop [31]. This includes: v) Reduce inputs, stored at a local host, and vi) Reduce outputs, stored on HDFS.

Task Suspend: We modify YARN so that the reduce task keeps track of two pieces of state: paths to files in the local filesystem which hold reduce input, and the key counter, i.e., number of keys that have been processed by the reduce function so far. When a reduce task receives a suspend request from its AM, the task checks if it is in the middle of processing a particular key, and finishes that key. Second it writes the input file paths to a local log file. Third, Hadoop maintains a *partial output file* per reduce attempt, in the HDFS distributed file system. This holds the output so far from that attempt. We name this partial output file so it includes the container id. When a task suspends, this partial output file is closed. Finally the reduce compiles its checkpoint and sends this to its AM. Then the reduce task exits.

Task Resume: On a resume, the task's AM sends the saved checkpoint state as launch parameters to the chosen NM. The Preemptor is in charge of scheduling the resuming reduce on a node. The Preemptor prefers the old node on which the last attempt ran (available from the hostname field in the checkpoint). If the resumed task is assigned to its old node, the reduce input can be read without network overhead, i.e., from local disk. If resumed on a different node, the reduce input is assembled from map task outputs, akin to a new task.

Next the reduce task creates a new partial output file in HDFS. It skips over those input keys that the checkpoint's key counter field indicates have already been processed. It then starts execution as a normal reduce task.

Commit after Resume: When a previously suspended reduce task finishes, it needs to assemble its partial output. It does so by first finding, in HDFS, all its past partial output files by using the ordered list of past suspended container ids from its checkpoint. It then accumulates their data into output HDFS files named in that order. This order is critical so that the output is indistinguishable from a reduce task that was never suspended.

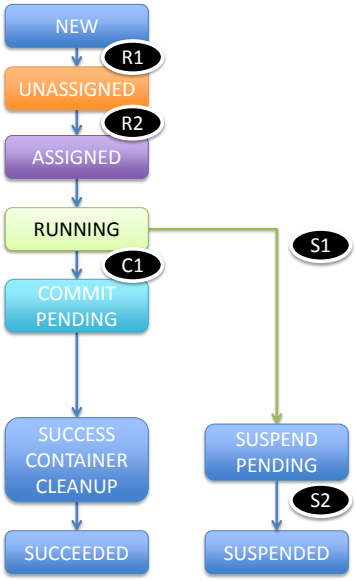

Figure 2: Modified Task Attempt State Machine: *At Application Master. Failure states are omitted.*

3.2 Implementation Issues

This section first describes how we modify the AM state machines in Hadoop YARN. We then detail the Preemptor and Releaser. As mentioned earlier, we leverage existing Hadoop mechanisms such as heartbeats.

Application Master's State Machines: For job and task management, Hadoop YARN's AM maintains separate state machines per job, per task, and per task attempt. Natjam does not change the job state machine – we only enabled this state machine to handle the checkpoint. Thus suspend and resume both occur during the *Running* state in this state machine.

We modify the task state machine minorly. When the AM learns that a task attempt has been suspended (from Step 8 in Fig 1), the task state machine goes ahead and creates a new task attempt to resume the task. However, this does not mean the task is scheduled immediately – the transitions of the task attempt state machine determine this.

The task attempt state machine is used by YARN to assign the container, set up execution parameters, monitor progress, and commit output. Natjam adds two states to the task attempt state machine, as shown in Fig. 2: *Suspend-Pending* and *Suspended*. The task attempt has a state of Suspend-Pending when it wishes to suspend a task but has not received suspension confirmation from the local task (Steps 6b-7 from Fig. 1). The state becomes Suspended when the saved checkpoint is received (Step 8) – this is a terminal state for that task attempt.

The new transitions for suspension in Fig. 2 are:

- S1: AM asks task to suspend, and requests checkpoint.
- S2: AM receives task checkpoint; saves it in task attempt state machine.

A resuming reduce task starts from the *New* state in the task attempt state machine. However, we modify some transitions to distinguish a resuming task from a new (non-resuming) task attempt:

- R1: Like for any reduce task attempt, every heartbeat from the AM to RM requests a container for the resuming reduce. If the RM cannot satisfy the request, it ignores it (since the next heartbeat will resend the request anyway). Suppose a container frees up (e.g., as production jobs complete), so that the RM can now schedule a research task. In doing so, the RM prefers responding to a resuming reduce's request, over one from a non-resuming research reduce. The AM to RM requests also carry the hostname field from the task checkpoint – the RM uses this to prefer container allocation at that hostname.
- R2: Once the AM receives a container from the RM, it launches a task attempt on the allocated container. For resuming reduces, the AM also sends the saved checkpoint to the container.
- C1: On commit, the AM accumulates partial output files into the final task output in HDFS (Section 3.1).

Preemptor: Recall that Natjam sets up the RM's Capacity Scheduler with two queues – one for production jobs and one for research jobs. The Preemptor is implemented as a thread within the Capacity Scheduler. In order to reclaim resources from the research queue for use by the production queue, the Preemptor periodically runs a *reclaim algorithm*, with sleeps of 1 s in between runs. A run may generate *reclaim requests*, each of which is sent to some research job's AM to reclaim a container (this is Step 4 in Fig 1). Intuitively, a reclaim request is a production job's intention of acquiring a container.

We keep track of a *per-production job reclaim list*. When the RM sends a reclaim request on behalf of a job, an entry is added to the job's reclaim list. When a container is allocated to that job, said reclaim list entry is removed. The reclaim list is essential to prevent the Preemptor from generating duplicate reclaim requests, which might occur because our reliance on heartbeats entails a delay between a container suspension and its subsequent allocation to a new task. Thus we generate a reclaim request whenever: (1) the cluster is full, and (2) the number of pending container requests from a job is greater than the number of requests in its reclaim list.

In extreme cases, the Preemptor may need to kill a container, e.g., if the AM has remained unresponsive for too long. Our threshold to kill a container is when a reclaim request has remained in the reclaim list for longer than a killing timeout (12 s). A kill request is sent di-

rectly to the NM to kill the container. This bypasses the AM, ensuring the container will indeed be killed. When a kill request is sent, the reclaim request is added to an expired list. It remains there for an additional time interval (2 s), after which it is assumed the container is dead, and the reclaim request is thus removed from the expired list. With these timeouts, we never observed any tasks killed in any of our cluster runs.

Releaser: The Releaser runs at each job's AM and decides which tasks to suspend. Since the task eviction policies of Section 2.2 (e.g., SRT, LRT) use time remaining at the task, the Releaser needs to estimate this. We use Hadoop's default exponentially smoothed task runtime estimator which relies on the task's observed progress [57]. However, calculating this estimate on-demand can be expensive due to the large numbers of tasks. Thus we have the AM only periodically estimate the progress of all tasks in the job (once a second), and use the latest complete set of estimates for task selection. While these might be stale, our experiments show that this approach works well in practice.

Interaction with Speculative Execution: The discussion so far has ignored speculative execution which Hadoop uses to replicate straggler task attempts. Natjam does not change speculative execution and works orthogonally, i.e., speculative task attempts are candidates for eviction. When all attempts of a task are evicted, the progress rate calculation of that task is not skewed. This is because speculative execution tracks progress of task attempts rather than tasks themselves. While this interaction could be optimized further, it works well in practice. Natjam can of course be further optimized to support user-defined (i.e., per-job) task eviction policies which would preferably evict speculative tasks – however this is outside our scope here.

4 Natjam-R: Deadline-based Eviction

We present Natjam-R, a generalization of Natjam, targeted at environments where each job has a hard and fixed real-time deadline. Unlike Natjam which allowed only two priority levels, Natjam-R supports multiple priorities – in the real-time case, a job's priority is derived from its deadline. While Natjam supported inter-queue preemption (with two queues), Natjam-R uses only *intra-queue* preemption. Thus all jobs can be put into one queue – there is no need for two queues. Jobs in the queue are sorted based on priority.

Eviction Policies: Firstly, for job eviction, we explore two deadline-based policies. These are inspired by classical real-time literature [17, 34] and they are *Maximum Deadline First (MDF)* and *Maximum Laxity First (MLF)*. MDF chooses as victim that running job which has the longest deadline. On the other hand, MLF evicts the job with the highest laxity, where *laxity* = *deadline* minus *job's projected completion time*. For MLF we extrapolate Hadoop's reported job progress rate to calculate a job's projected completion time.

Job	# Reduces	Avg Time (s)
Research-XL	47	192.3
Research-L	35	193.8
Research-M	23	195.6
Research-S	11	202.6
Production-XL	47	67.2
Production-L	35	67.0
Production-M	23	67.6
Production-S	11	70.4

Figure 3: Microbenchmark Settings.

While MDF is a static scheduling policy that accounts only for deadlines, MLF is a dynamic policy that also accounts for a job's resource needs. MLF may give a job, which has an unsatisfactory progress rate, more resources closer to its deadline. It may do so by evicting small jobs with long deadlines. In essence, while MLF may run some long-deadline-high-resource jobs, MDF might starve all long-deadline jobs equally. Further, MLF is fair in that it allows many jobs with similar laxities to make simultaneous progress. However, this fairness can be a shortcoming in scenarios with many short deadlines – MLF results in many deadline misses, while MDF would meet at least some deadlines. Section 7 experimentally evaluates this issue.

Secondly, our task eviction policies remain the same as before (SRT, LRT). This is because the deadline is for the job, not for individual tasks.

In addition to the job and task eviction policies, we need to have a job selection policy. When resources free up, this policy selects a job from among suspended ones and gives it containers. Possible job selection policies are Earliest deadline first (EDF) and Least laxity first (LLF). In fact we implemented these, but discovered thrashing-like scheduling behavior if the job eviction policy was inconsistent with the job selection policy. For instance, if we used MDF job eviction and LLF job selection, a job selected for eviction by MDF would soon after be selected for resumption by LLF, and thus enter a suspend-resume loop. We concluded that the job selection policy needed to be dictated by the job eviction policy, i.e., MDF job eviction implies EDF job selection, while MLF implies LLF job selection.

Implementation: The main changes in Natjam-R compared to Natjam are in the RM (Resource Manager). The RM now keeps one Capacity Scheduler queue sorted by decreasing priority. A priority is inversely proportional to deadline for MDF, or to laxity for MLF. The Preemp-

tor periodically (once a second) examines the queue and selects the first job (say J_i) that still has tasks waiting to be scheduled. Then it considers job eviction candidates from the queue, starting with the lowest priority (i.e., later deadlines or larger laxities) up to J_i's priority. If it encounters a job that still has allocated resources, it is picked as victim, otherwise no further action is taken. In the former case, the Releaser from Natjam uses the task eviction policy to free a container. Checkpointing, suspend, and resume work as described earlier for Natjam (Section 3).

5 Microbenchmarks

Experimental Plan: We present four sets of experiments, increasing in complexity and scale. This section presents microbenchmarking results for a small Natjam cluster. Section 6 evaluates a small Natjam deployment driven by real Hadoop traces. Section 7 evaluates Natjam-R. Finally, Section 8 evaluates a large Natjam deployment under real Hadoop traces.

Microbenchmark Setup: We first evaluate the core Natjam system that supports a dual priority workload, i.e., research and production jobs. We address the following questions: i) How beneficial is Natjam over existing techniques? ii) What is the overhead of the Natjam suspend mechanism? iii) What are the best job eviction and task eviction policies?

We used a small-scale testbed and a representative workload. This is because this first experimental stage involved exploring different parameter settings and studying many fine-grained aspects of system performance – a small testbed allowed us flexibility.

Our test cluster had 7 servers running on a 1 GigE network. Each server had two quad-core processors and 16 GB of RAM, of which 8 GB were configured to run 1 GB-sized Hadoop containers (thus 48 containers were available in the cluster). One server acted as Resource Manager while the other six were workers. Each entity (AM, map task, and reduce task) used one container.

Our experiments inject a mix of research and production jobs, as shown in Fig. 3. To reflect job size variation, job sizes range from XL (filling the entire cluster) to S (filling a fourth of the cluster). To mimic use case studies [58], each job had a small map execution time, and was dominated by reduce execution time. To model variance in task running times, reduce task lengths were selected uniformly from the interval $(0.5, 1.0]$, where 1.0 is the normalized largest reduce task. To emulate computations, we used SWIM [10] to create random keys and values, with thread sleeps called in between keys. Shuffle and HDFS traffic were incurred as usual.

The primary metric is job completion time. Each of our datapoints show an average and standard deviation over five runs. Unless otherwise noted, Natjam used MR job eviction and SRT task eviction policies.

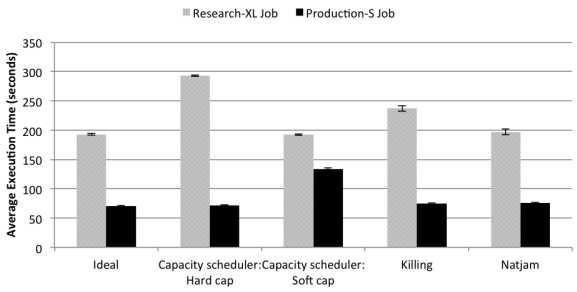

Figure 4: Natjam vs. Existing Techniques. *At t=0s Research-XL job submitted and at t=50s Production-S job.*

Natjam vs. Existing Techniques: Fig. 4 compares Natjam against several alternative settings: i) vs. an ideal setting, ii) vs. two existing mechanisms in the Hadoop Capacity scheduler, and iii) vs. pessimistically killing tasks instead of saving the cheap checkpoint. The ideal setting (i) measures each job's completion time when it is executed on an otherwise empty cluster; thus it ignores resource sharing and context switch overheads. For (ii) we chose the Hadoop Capacity Scheduler because it represents approaches that we might take with two physically-separate clusters sharing the same scheduler. Finally, killing of tasks (iii) is akin to approaches like [11] and the Hadoop Fair Scheduler [24].

In this experiment, a Research-XL job was submitted initially to occupy the entire cluster. Then, 50 s later a Production-S job was submitted. Fig. 4 shows that killing tasks (fourth pair of bars) finishes production jobs fast, but prolongs research jobs by 23% compared to the ideal (first pair of bars). Thus, saving the overhead of checkpoint is not worth the repeated work due to task restarts.

We next examine two popular Hadoop Capacity Scheduler approaches called *Hard cap* and *Soft cap*. Recall that the Capacity Scheduler allows the administrator to set a maximum cap on the capacity allocated to each queue (research and production). In Hard cap, this capacity is used as a hard limit for each respective queue. In the Soft cap approach, each queue is allowed to expand to the full cluster if there are unused resources, but it cannot scale down without waiting for its scheduled tasks to finish (e.g., if the production queue needs resources from the research queue). We configured these two approaches with the research queue set to 75% capacity (36 containers) and production queue to 25% capacity (12 containers), as these settings performed well.

Fig. 4 shows that in Hard cap (second pair of bars), the research job takes 52% longer than ideal, while the production job stays unaffected. Under Soft cap (third pair of bars), the production job can obtain containers

Task Eviction Policy	Production Job	Mean (s.d.) run time, in s	Research Job	Mean (s.d.) run time, in s
Random	Production-S	76.6 (3.0)	Research-XL	237.6 (7.8)
LRT	Production-S	78.8 (1.8)	Research-XL	247.2 (6.3)
SRT	Production-S	75.6 (1.5)	Research-XL	197.0 (5.1)
Random	Production-L	75.0 (1.9)	Research-XL	244.2 (5.6)
LRT	Production-L	75.8 (0.4)	Research-XL	246.6 (6.8)
SRT	Production-L	74.2 (1.9)	Research-XL	234.6 (3.4)

Figure 5: Task Eviction Policies: *At t=0s, a Research-XL job is submitted; at t=50s the production job is submitted. Job completion times are shown. The ideal job completion times are shown in Fig. 3.*

only when the research job frees them – this results in an 85% increase in production job completion time, while the research job stays unaffected.

The last pair of bars shows that when using Natjam, the production job's completion time is 7% worse (5.4 s) than ideal, and 77% better than Hadoop Capacity Scheduler Soft cap. The research job's completion time is only 2% worse (4.7 s) than ideal, 20% better than that of Killing, and 49% better than Hadoop Hard cap. One of the reasons the research job is close to ideal is that it is able to make progress parallelly with the production job. There are other internal reasons for this performance benefit – we explore these next.

Suspend overhead: We measured Natjam's suspend overhead on a fully loaded cluster. We observed that it took an average of 1.35 s to suspend a task and 3.88 s to resume a task. Standard deviations were low. In comparison, default Hadoop took an average 2.63 s to schedule a task on an empty cluster. From this it might appear that Natjam incurs a higher total overhead of 5.23 s per task suspend-resume. However, in practice the effective overhead is lower – for instance, Fig. 4 showed only a 4.7 s increase in research job completion time. This is because typically task suspends occur in parallel and in some cases task resumes do too. Thus these time overheads are parallelized rather than aggregated.

Task eviction policies: We now compare the two task eviction policies (SRT, LRT) from Section 2.2 against each other, and against a random eviction strategy that we also implemented. We performed two sets of experiments, one with Production-S and another with Production-L. This production job was injected 50 s after a Research-XL job.

Fig. 5 tabulates the results. In all cases the production job incurred similar overhead compared to an empty cluster. Thus we discuss only research job completion time (last column). In the top half of the table, a random task eviction strategy results in a 45 s increase in completion time compared to ideal – we observed that a fourth of the tasks were suspended, leading to a long job tail. Evicting the longest remaining task (LRT) incurs a higher increase of 55 s – this is because LRT prolongs the tail. Evicting the shortest remaining task (SRT) emerges as the best policy and is only 4.7 s worse than ideal because it respects the job tail.

In the lower half of Fig. 5, a larger production job causes more suspensions. The research job completion times by the random and LRT eviction policies are similar to the top half – this is because its tail was already long with a small production job, and does not grow much for this case. SRT is worse than with a small production job, yet it outperforms the other two eviction strategies.

We conclude that SRT is the best task eviction policy, especially when production jobs are smaller than research jobs. We believe this is a significant use case since research jobs run are longer and process more data, while production jobs are typically small due to the need for faster results.

Job eviction policies: We next compare the three job eviction policies of Section 2.1. Based on the previous results, we always used SRT task eviction [5]. We initially submitted two research jobs, and 50 s later a small production job. We examine two settings – one where the initial research jobs are comparable in size and another where they are different. We observed the production job completion time was close to ideal, hence Fig. 6 only shows research job completion times.

The top half of Fig. 6 shows that when research job sizes are comparable, probabilistically weighing job evictions by resources (PR) and evicting the job with the most resources (MR) perform comparably – research job completion times stay within 2 s (0.5%) between the two policies. This is desirable due to the matching job sizes. However, evicting the job with the least resources (LR) performs worst because it causes starvation in one of the jobs – once tasks start getting evicted from a research job (which may be picked randomly by LR at first if all jobs have the same resource usage), LR subsequently always picks the same job (until it is fully suspended).

This behavior of LR is even more pronounced on small research jobs in a heterogeneous mix, as in the bottom half of Fig. 6. The Research-S job is picked as victim by PR less often than by LR, and thus PR outperforms LR. PR penalizes the Research-L job slightly more than LR since PR evicts more tasks from a larger

[5] Using LRT always turned out to be worse.

Job Eviction Policy	Research Job	Mean (s.d.) run time, in s	Research Job	Mean (s.d.) run time, in s
PR	Research-M	195.8 (1.3)	Research-M	201.2 (0.8)
MR	Research-M	196.2 (1.3)	Research-M	200.6 (2.1)
LR	Research-M	200.6 (1.3)	Research-M	228.8 (12.7)
PR	Research-L	201.6 (8.3)	Research-S	213.8 (18.8)
MR	Research-L	195.8 (1.1)	Research-S	204.8 (2.2)
LR	Research-L	195.8 (0.4)	Research-S	252.4 (9.3)

Figure 6: Job Eviction Policies: *At t=0s two research jobs are submitted (two Research-M's, or Research-S and Research-L); at t=50s Production-S job submitted. Only research job completion times shown. The ideal job completion times are shown in Fig. 3.*

job. Even so, PR and MR are within 10 s (5%) of each other – any differences are due to the variable task lengths, and the effectiveness of the SRT task eviction policy. We observed that MR evicted no tasks at all from the Research-S job.

We conclude that when using the best task eviction policy (SRT), the PR and MR job eviction policies are more preferable over LR, with MR especially good under heterogenous mixes of research job sizes.

6 Small-scale Deployment

This section presents experiments that answer the following questions under a real Hadoop workload for the dual priority setting: i) What is Natjam's realistic benefit? ii) How does Natjam compare to the Hadoop Capacity scheduler Soft cap, and to Killing of tasks? iii) How does Natjam impact production job completion times?

Setup: We obtained traces from a Yahoo production cluster and from a Yahoo research cluster, containing several hundreds of servers. While we cannot reveal details of these traces due to confidentiality, we discuss them briefly. The traces cover thousands of job submissions over several hours. They include job submission times, job sizes, number of maps, number of reduces, and other information. The jobs are of different sizes, the arrivals are bursty, and the load varies over time – thus this trace captures a realistic mix of conditions.

We injected 1 hour of traces with about 400 jobs into our 7-server test cluster (Section 5) configured with 72 containers (12 for each worker). Natjam used MR job eviction and SRT task eviction. Due to the smaller size of the target cluster we scaled down the number of tasks in each job. To mimic a workload similar to that faced by the original larger cluster, we used different scaling factors for the production and research traces. The production scaling factor was chosen to prevent the production jobs from just overloading the cluster at its peak. The research job scaling factor was chosen so it overloaded the cluster. This effectively allows us to keep resource utilization high and use job completion time as the main metric. Jobs were then submitted at the times indicated by the trace. The tasks were emulated using SWIM [10],

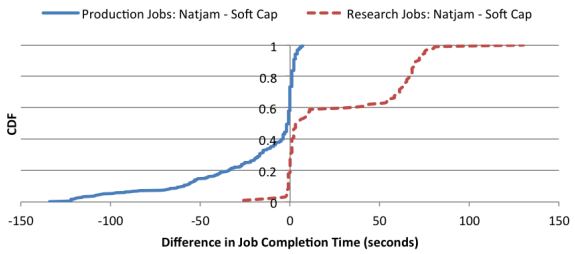

Figure 7: Small Deployment: Natjam vs. Soft Cap. *Negative values imply Natjam is better.*

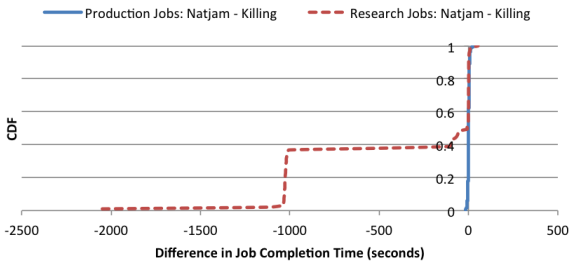

Figure 8: Small Deployment: Natjam vs. Killing.

incurring the usual shuffle and HDFS traffic.

The results are depicted in Fig. 7 to 9. Each plot compares Natjam vs. an alternative strategy *A*. We calculated, for each job j_i the quantity = *(Completion time for j_i in the Natjam cluster)* minus *(Completion time for j_i in the A cluster)*. We then plot the CDF of this quantity. Negative values on the CDF imply Natjam completes the job earlier than the alternative strategy.

Natjam vs. Soft Cap: We configured the Hadoop Capacity Scheduler Soft cap with 80% capacity for production and 20% for research jobs – recall that this mechanism allows the allocated capacities for each class to scale up to the full cluster. Fig. 7 shows that compared to the Soft cap approach, with Natjam 40% of production jobs finish at least 5 s earlier, 20% finish 35 s earlier, and 10% finish 60 s earlier. Only 3% of production jobs perform 5 s or worse with Natjam. In fact, 60% of research jobs are delayed 30 s or less. We believe this is a reasonable tradeoff to accommodate production jobs.

Natjam vs. Killing: Fig. 8 shows that compared to the cheaper approach of killing research jobs, saving their

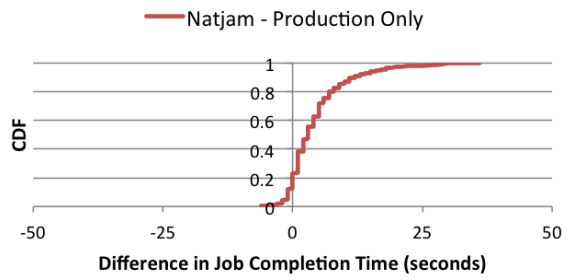

Figure 9: Small Deployment: Natjam vs. Production Only.

checkpoint in Natjam tremendously improves research job completion times. 36% of research jobs finish at least 1000 s earlier.

Natjam does not affect production jobs much, compared to Killing. The mean and median are within a second of each other, and the absolute decrease and increase in performance at the 1st percentile and 99th percentile are within 2 s. We conclude that even under a realistic workload, checkpointing is preferable to killing tasks.

Natjam vs. Production Only: To isolate Natjam's effect on production jobs, we compared two clusters – a Natjam cluster receiving the production + research trace as above, and a Hadoop cluster (Soft Cap) receiving only the production job part of the trace (labeled Production Only). Fig. 9 shows that for production jobs, the median Natjam job is within 3 s of Production Only's median, while the mean is within 4.5 s of Production Only.

The maximum difference in completion time is 36 s. This high value due to two factors. First is Natjam's overhead for suspending tasks (Section 5). Second is an implementation bottleneck arising out of Natjam's Hadoop integration where concurrent requests for starting AMs are serialized. These factors were amplified because of the small cluster size – they disappear in Section 8 where a large cluster leads to a higher rate of containers becoming free.

7 Natjam-R Evaluation

We now evaluate the real-time support of our Natjam-R system (Section 4). Our experiments address the following questions: i) How do MDF and MLF job eviction strategies compare? ii) How good is Natjam-R at meeting deadlines? iii) Do Natjam-R's benefits hold under realistic workloads?

We use 8 Emulab servers [18, 54], each with 8 core Xeon processors and 250 GB disk space. One server is the Resource Manager, and each of the other seven servers runs 3 containers of 1 GB each (thus 21 containers total).

MDF vs MLF: We injected three identical jobs, Job 1 to Job 3, each with 8 maps and 50 reduces (each job took 87 s on an empty cluster). They were submitted in that order starting at t=0 s and 5 s apart, thus overloading the cluster. Since MDF and MLF will both meet long deadlines, we chose shorter deadlines. To force preemption, the deadlines of Job 1 to Job 3 were set 10 s apart – 200 s, 190 s and 180 s respectively.

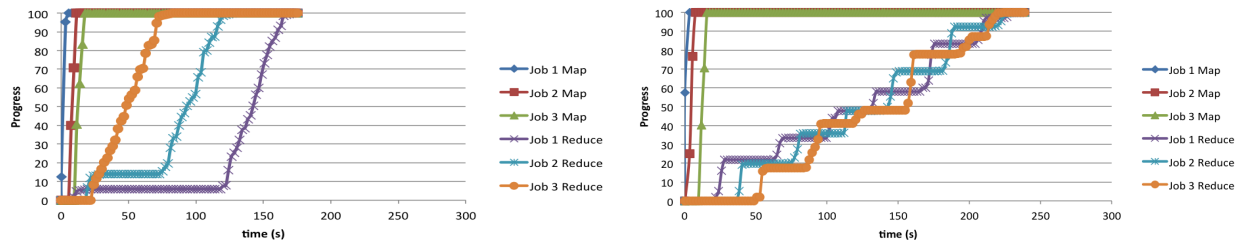
Fig. 10 depicts the progress rate for the MDF cluster and the MLF cluster. Our first observation is that while MDF allows the short deadline jobs to run earlier and thus satisfy all deadlines, MLF misses all deadlines in Fig. 10b. In MLF, jobs proceed in lockstep after a while in the reduce phase – this occurs because when a lower laxity job (e.g., Job3) has run for a while in lieu of a higher laxity job (e.g., Job1), their laxities become comparable. Thereafter, each job alternately preempts the other. Breaking ties, e.g., by using deadline, does not eliminate this behavior. In a sense, MLF tries to be fair to all jobs allowing them all to make progress simultaneously, but this fairness is in fact a drawback.

MLF also takes longer to finish all jobs, i.e, 239 s compared to MDF's 175 s. Basically, MLF's lockstep behavior incurs a high context switch overhead. We conclude that MDF is preferable to MLF, especially under short deadlines.

Varying the Deadline: We submitted a job (Job 1) same as the above, and 5 s later an identical job (Job 2) whose deadline is 1 s earlier than Job 1's. For Job 1 we measured its *clean compute time* as the time to run the job in an empty cluster. Then, we set its *deadline = submission time + (clean compute time* $\times$ *(1+*ε*))*. Fig. 11 shows the effect of ε on a metric called *margin*. We define a job's *margin = (deadline)* minus *(job completion time)*. A negative margin implies a deadline miss. We observe that an ε as low as 0.8 still meets both deadlines, while an ε as low as 0.2 meets at least the shorter deadline. This means that given one critical job with a very short deadline, Natjam-R can satisfy it if it has at least 20% more time than the job's clean compute time. This number is thus an estimate of Natjam-R's overhead. We also performed experiments which varied the second job's size as a fraction of the first job from 0.4 to 2.0, but we saw little effect on margin.

Trace-Driven Experiments: We used the Yahoo! Hadoop traces earlier from Section 6 to evaluate Natjam-R's deadline satisfaction. We used only the production cluster trace, scaled so as to overload the target cluster. Since the original system did not support deadline scheduling, no deadlines were available from the traces. Thus we chose ε randomly for each job from the interval $[0, 2.0]$, and used this to set its deadline forward from its submission time (as described earlier). A given job's deadline was selected to be the same in all runs.

Fig 12 compares Natjam-R against Hadoop Soft cap. It shows the CDF of the difference in the margins of the



(a) (b)

Figure 10: Natjam-R: (a) MDF vs. (b) MLF. *Lower index jobs have shorter deadline but arrive later.*

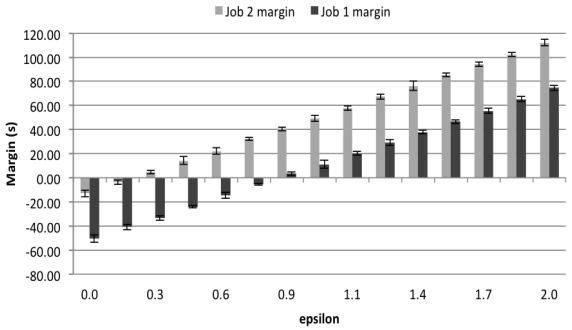


Figure 11: Natjam-R: Effect of Deadlines*: Margin = Deadline - Job completion time, thus a negative margin implies a deadline miss. Job 2 has a deadline 1 s earlier but is submitted 5 s after Job 1.*

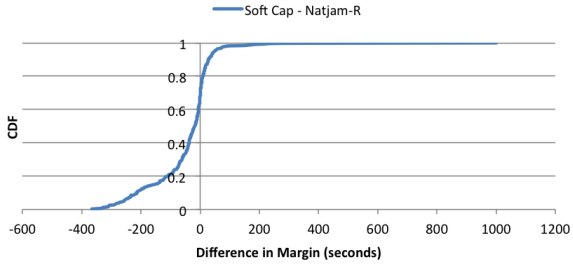

Figure 12: Natjam-R: Effect of real Yahoo! Hadoop Trace*: Margin = Deadline - Job completion time. Negative values imply Natjam-R is better.*

two approaches – a negative difference implies Natjam-R is better. Natjam-R's margin is better than Soft cap's for 69% of jobs. The largest improvement in margin was 366 s. The plot is biased by one outlier job that took 1000 s longer in Natjam-R; the next outlier is only -287 s. This outlier job suffered in Natjam-R because the four jobs submitted just before it and one job right after had much shorter deadlines. Yet the conclusion is positive – among the 400 jobs with variable deadlines, there was only one such outlier. We conclude that Natjam-R satisfies deadlines well under a realistic workload.

8 Large-scale Deployment

Finally, we return to the dual priority Natjam, and evaluate it on a real Yahoo datacenter. We address the

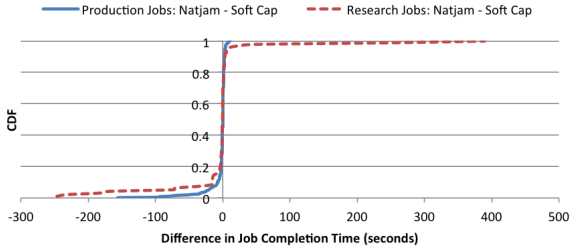

Figure 13: Large-scale Deployment: Natjam vs. Hadoop Soft Cap. *Negative values imply Natjam is better.*

same questions as Section 6 but for a larger deployment setting. The target Yahoo datacenter consisted of 250 servers, configured to run a total of 2000 containers. We used the Yahoo! Hadoop traces of Section 6 scaled to the cluster. The total shuffle traffic was measured at about 60 GB, and HDFS incurred 100 GB read and 35 GB write.

Natjam vs. Soft Cap: Fig. 13 shows that for production jobs, Natjam completes 53% of jobs earlier than Hadoop Soft cap. Further, 12% of these jobs finish at least 5 s earlier than in Soft cap, and fewer than 3% jobs finish 5 s or later. In fact we observe that at the 5th percentile jobs finish 20 s or earlier, at the 2nd percentile 60 s or earlier, and at the 1st percentile 80 s or earlier. The largest improvement over Soft cap is more than 150 s.

In Natjam production jobs take resources away research jobs. Yet, Natjam completes 63% of research jobs earlier than in Soft cap. This might appear to be non-intuitive to the reader, but is explained as follows – most research jobs benefit due to Natjam, but this comes at the expense of a few research jobs that get starved. Yet, the number of such starved outliers is small – the top right part of the research jobs curve Fig. 13 is due to only two outlier jobs that were 260 s and 390 s slower.

Natjam vs. Killing: Fig. 14 shows that compared to killing research jobs, Natjam's checkpointing improves research job completion times by over 100 s for 38% of jobs. At the 5th percentile Natjam is almost 750 s faster. The largest improvement was 1880 s. Natjam does not affect production jobs much – completion times for the two approaches are within 1 s of each other at the 99th

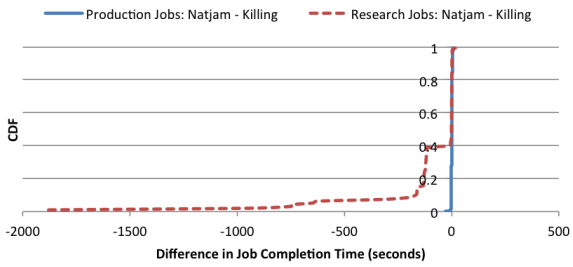

Figure 14: Large-scale Deployment: Natjam vs. Killing.

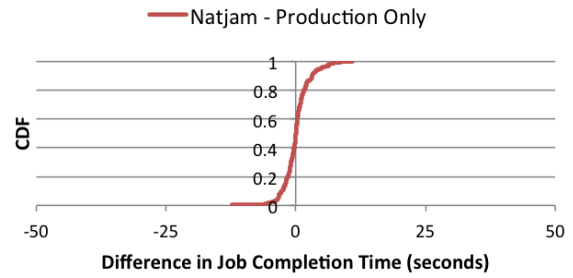

Figure 15: Large-scale Deployment: Natjam vs. Production Only.

and 1st percentiles.

Natjam vs. Production Only: Fig. 15 shows the median Natjam job completion time is within 40 ms of Production Only, while the mean is within 200 ms. Thus Natjam's checkpointing has minimal impact on production jobs.

We conclude that Natjam is preferable to Hadoop Soft cap for a large cluster under a real workload.

9 Discussion

We now discuss extensions, drawbacks, and issues.

Rack-level Locality: Currently in Natjam, a resumed task can reuse reduce input files only when it is scheduled on the same server as its last task attempt. Otherwise, network transfers are required from all map tasks. This could be ameliorated by instead saving the reduce checkpoint into HDFS. Globally accessible reduce input would allow a reduce to resume efficiently on any server. To decide where a task attempt resumes, a multi-level preference order would be used: first prefer the server of the last attempt, then a server in the same rack, and then any server. To lower overhead, HDFS could be modified to store only one replica of the checkpoint. In case of failure, reduce input could be obtained again from map tasks. HDFS would store this at the writing node itself, thus invoking only a local disk write.

Suspending Stateful Reduces: So far, Natjam supports only stateless reduces and does not require any changes to the user's Hadoop code. However, some Mapreduce tasks have stateful reduce tasks, i.e., the task saves state across keys. Natjam could support this via serialize and deserialize methods. When a task is suspended, inter-key state datastructures are serialized and copied to HDFS. When the task resumes, Natjam deserializes the checkpoint and skips to the current key counter. These two methods are application-dependent, hence the Hadoop programmer needs to write them – these UDFs could be invoked via a callback on suspension and resumption [41]. We believe that in many cases these could be written in such a way as to maintain small checkpoints. For instance, consider [33] which computes relative frequency across word co-occurrences. Reduce keys are co-occurring word pairs. A special key (w, Σ), used to compute the sum of all occurrences of w, appears just before all $(w, *)$ pairs. Each subsequent pair containing w is divided by this sum to derive the frequency. In Natjam, our serialize and deserialize methods would merely maintain an integer field to store this sum.

OS Mechanisms: Natjam does not rely on priorities at the OS level, or prohibitive integration with the OS – this follows the Hadoop philosophy. If this were done however, Natjam's responsiveness could be improved in several ways. First, shutting down a container and bringing a new one up are done sequentially today in Hadoop – overlapping and pipelining these could make them faster. Second, instead of piggybacking on heartbeats, higher priority control messages could be sent to make faster scheduling decisions.

Chained Jobs: Data analysis frameworks [38, 51] and workflow schedulers [39] create chains or DAGs of Hadoop-like jobs, where each DAG has one deadline. Natjam could be used to address this scenario by leveraging critical path-based algorithms [19, 45] to calculate deadlines of constituent Hadoop jobs, and ParaTimer [36] to estimate progress rate.

Priority Inversion: Priority-based schedulers often suffer from priority inversion, causing oscillatory scheduling between high and low priority tasks. Natjam and Natjam-R do not suffer from priority inversion, because resources can be preempted, thus violating one of the necessary conditions for priority inversion [8]. Higher priority tasks always win.

Fairness: Natjam and Natjam-R do not focus on fairness because their main goal is to prefer higher priority jobs over lower priority ones. Natjam is not immune to starvation of a few low priority jobs, e.g., if a higher priority job arrives whenever the victim task gets resumed. This results in variability in completion time among jobs. However, our experiments showed that most low priority jobs are affected very little and there are very few outlier jobs. An interesting future direction would be to design job eviction policies sensitive to previously-evicted jobs, however this may lead to priority inversion.

Preempting vs. Finishing: Our results have shown that as a general policy it is preferable to preempt reduces

rather than completing them (Soft cap). However, Natjam could be optimized further to make this decision on a per-task basis – if the leftover work is very little, the task would be completed instead of being preempted.

Guaranteeing Deadlines: Natjam-R only performs best-effort deadline-based scheduling, rather than admission control. Guaranteeing deadlines at job arrival time is a challenging problem in dynamic and constrained Mapreduce clusters, requiring job profiling and estimation [52], and careful worst-case assumptions.

10 Related Work

OS mechanisms: Sharing finite resources among applications is a fundamental issue in Operating Systems [50]. Not surprisingly, Natjam's eviction policies are analogous to multiprocessor scheduling techniques (e.g., shortest task first), and to eviction policies for caches and paged OSs. However, our results are different because Mapreduce jobs need to have all tasks finish. PACMan [4] looks at eviction policies for caches in Mapreduce clusters, and it can be used orthogonally with Natjam.

Preemption: Amoeba, a system built in parallel with ours, provides instantaneous fairness with elastic queues, and uses a checkpointing mechanism [6]. The main differences in Natjam compared to Amoeba are: i) we focus on job and task eviction policies, ii) we focus on jobs with hard deadlines, and iii) our implementation works directly with Hadoop 0.23, while Amoeba requires the prototype Sailfish system [43]. Further, Sailfish was built on Hadoop 0.20 – since then, Hadoop 0.23 has addressed many relevant bottlenecks, e.g., using read-ahead seeks, Netty [37] to speed up shuffle, etc. Finally, our eviction policies and scheduling can be implemented orthogonally in Amoeba.

Delay scheduling [58] avoids killing map tasks while achieving data locality. In comparison, Natjam focuses on reduce tasks as they are longer than maps, and they release resources slower – this makes our problem more challenging. Global preemption [11] selects tasks to kill across all jobs, which is suboptimal.

A recently started Hadoop JIRA issue [29] also looks at checkpointing and preemption of Reduce tasks. Such checkpointing can be used orthogonally with our eviction policies, which comprise our primary contribution. Finally, Piccolo [41] is a data processing framework that uses checkpointing based on consistent global snapshots – in comparison, Natjam's checkpoints are local.

Real-time Scheduling: ARIA [52] and Conductor [55] estimate how a Hadoop job needs to be scaled up to meet to its deadline, e.g., based on past execution profiles or a constraint satisfaction problem. They do not target clusters with finite resources. Real-time constraint satisfaction problems were solved analytically [40], and Jockey [19] addressed DAGs of data-parallel jobs – however eviction policies or Hadoop integration were not fleshed out. Statistics-driven approaches have been used for cluster management [20] and for Hadoop [30]. Much work has also been done in speeding up Mapreduce environments by tackling stragglers, e.g., [5, 57], but these do no not support job priorities.

Dynamic proportional share scheduling [44] allows applications to bid for resources, but is driven by economic metrics rather than priorities or deadlines. The network can prioritize data for time-sensitive jobs [12], and Natjam can be used orthogonally.

Natjam focuses on batch jobs rather than stream processing or interactive queries. Stream processing in the cloud has been looked at intensively, e.g., Hadoop Online [13], Spark [48], Storm [49], Timestream [42] and Infosphere [26]. BlinkDB [2] and MeT [14] optimize interactive queries for SQL and NoSQL systems.

Finally, classical work on real-time system has proposed a variety of scheduling approaches including classical EDF and rate monotonic scheduling [34, 35], priority-based scheduling of periodic tasks [21], laxity-based approaches [17], and handling task DAGs [45] – Natjam is different in its focus on Mapreduce workloads.

Fairness: Providing fairness across jobs has been a recent focus in cloud computing engines. This includes Hadoop's Capacity Scheduler [23] and Fair Scheduler [24], which provide fairness by allowing an administrator to configure queue capacities and job priorities. These do not allow resource preemption [28]. Quincy [27] solves an optimization problem to provide fairness in DryadLinq [56]. Quincy does consider preemption, but neither proposes eviction policies nor checkpointing mechanisms. Finally, there has been recent focus on satisfying SLAs [7] and satisfying real-time QoS [3] but these do not target Mapreduce clusters.

Cluster Management with SLOs: Recent cluster management systems have targeted SLOs, e.g., Omega [46], Cake [53], Azure [9], Centrifuge [1] and Albatross [15]. Mesos [32] uses dominant resource fairness across applications sharing a cluster, and Pisces [47] looks at multi-tenant fairness in key-value stores.

11 Summary

This paper presented Natjam and its generalization Natjam-R, which provide support for dual priorities and hard-real time scheduling, for jobs in constrained Mapreduce clusters. Among several eviction policies we found that the MR (Most Resources) job eviction and SRT (shortest remaining time) task eviction policies are the best for the dual priority setting. For the hard-real time setting, the MDF (maximum deadline first) job eviction policy performed the best. Natjam incurs only a 2-7% context switch overhead. Natjam-R meets dead-

lines with only 20% extra laxity in deadline. Natjam and Natjam-R perform better than existing approaches for a variety of clusters, sizes, and under a real workload.

Acknowledgments: We are grateful to our anonymous reviewers, our shepherd Rodrigo Fonseca, and John Wilkes, for their advice and insightful comments.
